Review

String formatting

formats the specified value(s) and insert them inside the string's placeholder.

- **F-strings (python +3.6):** exp: `f"hello {name}"`
- **.format() string method (new):** exp: `"hello {}".format(name)`
- **% operator (old):** exp: `"hello %s" % name`

```
name = 'Akbar'
age = 21

print("Hello "+name+' (Age:'+str(age)+')')
print(f"Hello {name} (Age:{age})")
print("Hello {} (Age:{}".format(name, age))
print("Hello {1} (Age:{0})".format(age, name))
print("Hello {name} (Age:{age})".format(age=age, name=name))
print("Hello %s (Age:%d)" % (name, age))
print("Hello %s (Age:%d)" % (name, age))
```

range() function

Generate a sequence of numbers: **range(...)**

- **range(stop):** exp: range(5) -> 0, 1, 2, 3, 4
- **range(start, stop):** exp: range(5, 10) -> 5, 6, 7, 8, 9
- **range(start, stop, step):** exp: range(5, 10, 2) -> 5, 7, 9

```
print(type(range(1,2)))      # ?

for i in range(8):
    print(i, end=' ')        # end??

for i in range(1, 6, 2):
    print(i, end=', ')

numbers = list(range(0,10))  # Cast range() to list
print(numbers)               # ???
```

Else in loops

The else block just after for/while is executed only when the loop is **NOT** terminated by a **break** statement.

```
n = 10
_ = 0
while _ < n:
    print(_)
    if _ // 10:
        print('Breaking!')
        break
    _ += 1
else:
    print('Else part!')
print('Rest of program...')
```

Example: Is Primal

Primal number

Write a program that, gets a int & positive number,
Then prints that it's primal or not

Input 1:

51

Output 1:

False

Input 2:

23

Output 2:

True

Example: Is Primal

Primal number

Write a program that, gets a int & positive number,
Then prints that it's primal or not

```
n = int(input("Enter a number: "))

for _ in range(2, n):
    if n % _ == 0:
        print('False')
        break
else:
    print('True')
```

Chapter 9

Functions

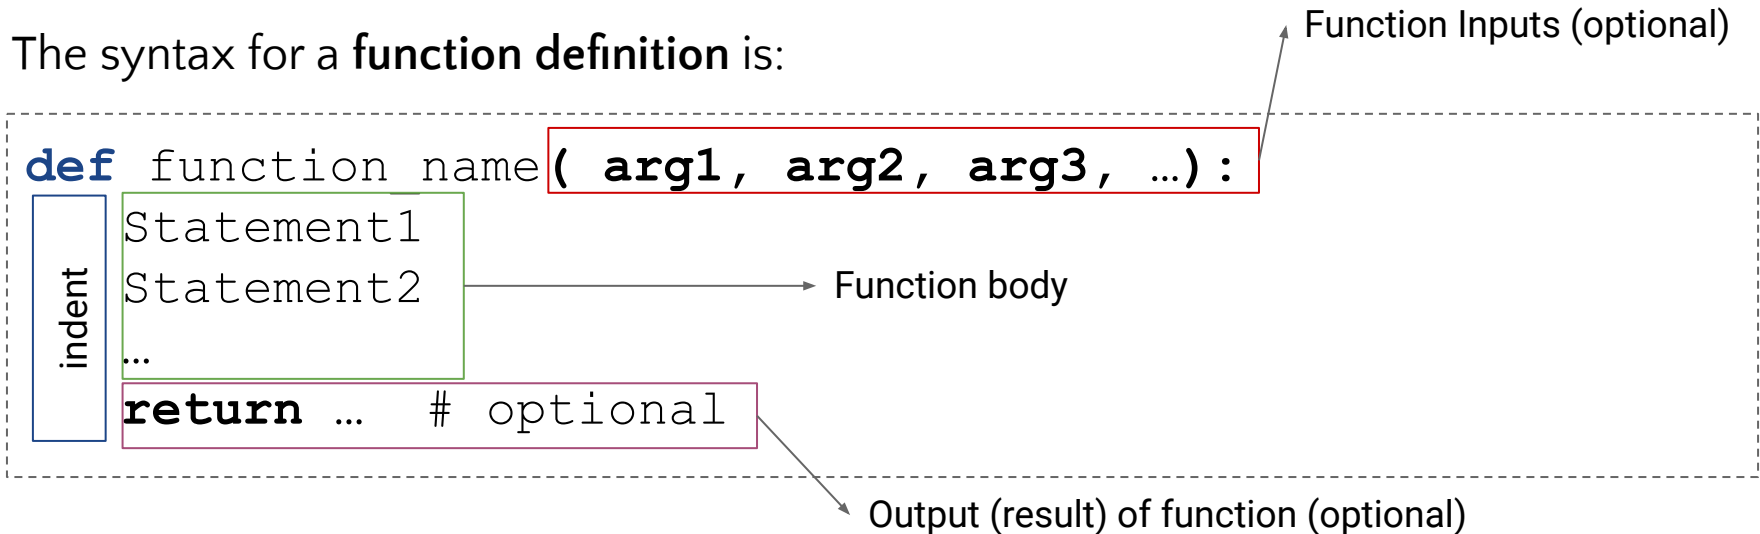

Define a function

In Python, a **function** is a named sequence of statements that belong together. Their primary purpose is to help us organize programs into chunks that match how we think about the solution to the problem.

The syntax for a **function definition** is:

Define a function

In Python, a **function** is a named sequence of statements that belong together. Their primary purpose is to help us organize programs into chunks that match how we think about the solution to the problem.

The syntax for a **function definition** is:

Function return statement

A **return** statement is used to **END** the execution of the function call and “returns” the result (value of the expression following the return keyword) to the caller.

The statements after the return statements are **NOT** executed.

→ If the return statement is without any expression, then the special value **None** is returned.

```
def function_name( arg1, arg2, arg3, ...):  
    Statement1  
    Statement2  
  
    ...  
    return ... # optional
```

Output (result) of function (optional)

Function call

To call a function, use the function name followed by parenthesis.

```
def function_name( arg1, arg2, arg3, ...):  
    Statement1  
    Statement2  
    ...  
    return ... # optional  
  
result = function_name(1, 'akbar', True, ...)
```

Function Examples

Maktab
Sharif

Search It

pass in python

```
def hello_world():  
    print('Hello world')  
  
res = hello_world()  
print(type(res))  
print(res)
```

```
def pow(a, b):  
    return a ** b  
  
res = pow(2, 4)  
print(res)  
print(type(res))
```

```
def my_func(arg1, arg2, arg3):  
    print('> Start of function')  
    print(arg1, arg2, arg3)  
    return arg1, arg2, arg3  
    print('> End of function')
```

```
res = my_func('Akbar', 111, False)  
print(res, res[0], res[1], res[2])  
print(type(res))  #???
```

```
def pass_func(x, y):  
    pass  
  
print(pass_func(1, 2))
```

Optional arguments (default value)

Functions can have optional parameters, also called default parameters. Default parameters are parameters, which don't have to be given, if the function is called. In this case, the default values are used. We will demonstrate the operating principle of default parameters with an example. The following little script, which isn't very useful, greets a person. If no name is given, it will greet everybody:

```
def say_hello(name='Akbar'):  
    print('Hello', name, '!')
```

```
say_hello()  
say_hello('Reza')  
say_hello('World')
```

```
def pow(base, exponent=2):  
    return base ** exponent
```

```
print(pow(4))  
print(pow(2, 6))  
print(pow())
```

Example: Primal numbers

Primal number

Write a **function** that, gets a int & positive number (N),
Then prints primal numbers **between 1 and N**.

Input 1:

7

Output 1:

2, 3, 5, 7,

Input 2:

23

Output 2:

2, 3, 5, 7, 11, 13, 17, 19, 23,

Example: Primal numbers

Primal number

Write a **function** that, gets a int & positive number (N),
Then prints primal numbers **between 1 and N**.

```
# Part 1: is_primal function
def is_primal(n):
    for _ in range(2, n):
        if n % _ == 0:
            return False
    else:
        return True
```

```
# Part 2: main
N = int(input('Enter a number:'))

for n in range(2, N+1):
    if is_primal(n):
        print(n, end=', ')
```

Keyword arguments (Named parameters)

Using keyword parameters is an alternative way to make function calls. The definition of the function doesn't change.

An example:

```
def sum_sub(a, b, c=0, d=0):  
    return a - b + c - d  
  
print(sum_sub(12, 4))  
print(sum_sub(b=5, a=10))  
print(sum_sub(42, 15, 11, 10))  
print(sum_sub(42, 15, 0, 10))  
print(sum_sub(42, 15, d=10))  
print(sum_sub(b=2, 5, 4))
```

#???

Local and Global variables

Using keyword parameters is an alternative way to make function calls. The definition of the function doesn't change.

An example:

```
def square1(x):  
    y = x * x  
    return y
```

```
z = square1(10)  
print(y)
```

```
def square2(x):  
    y = x ** power  
    return y
```

```
power = 2  
result = square2(10)  
print(result)
```

Local and Global variables

Using keyword parameters is an alternative way to make function calls. The definition of the function doesn't change.

An example:

```
def func2():  
    x *= 10
```

```
x = 10  
func2()
```

```
def func1():  
    print(x)
```

```
x = 10  
func1()
```

What is your conclusion?

Example: Swap function

Swap function

Write a function that, gets 2 values
Then swaps them.

Inputs:

```
def swap(...):  
    ...  
  
a = 10  
b = 'Akbar'  
swap()  
print(a, b)
```

result:

```
Akbar 10
```

Example: Swap function

Swap function

Write a function that, gets 2 values

Then swaps them.

Using **global**:

```
def swap():  
    global a  
    global b  
    a, b = b, a
```

• Search It

Global in python

Example

What's result of code below

```
def hi_all(students_list, teacher_list):  
    teacher_list.extend(students_list)  
    for x in teacher_list:  
        print('> Hello', x, '!')  
  
teachers = ['Shahin', 'Amirhossein', 'MohammadAmin']  
students = ['Ali', 'Mohammad', 'Salar', 'Akbar', 'Nader']  
print('Before function:', students, teachers, '', sep='\n\t')  
hi_all(students, teachers)  
print('\nAfter function:', students, teachers, sep='\n\t')
```

Example

Maktab
Sharif

Why??

```
Before function:
```

```
['Ali', 'Mohammad', 'Salar', 'Akbar', 'Nader']  
['Shahin', 'Amirhossein', 'MohammadAmin']
```

```
> Hello Shahin !  
> Hello Amirhossein !  
> Hello MohammadAmin !  
> Hello Ali !  
> Hello Mohammad !  
> Hello Salar !  
> Hello Akbar !  
> Hello Nader !
```

```
After function:
```

```
['Ali', 'Mohammad', 'Salar', 'Akbar', 'Nader']  
['Shahin', 'Amirhossein', 'MohammadAmin', 'Ali', 'Mohammad', 'Salar', 'Akbar', 'Nader']
```

Chapter 10

Some built-in function

type(x)

The **type()** function returns the type of the specified object

```
print(type(""))  
print(type(124))  
print(type(124.5))  
print(type('124'))  
print(type([]))  
print(type(True))  
print(type(range(5)))  
print(type(str('123')))
```

len(...)

The **len()** function returns the number of items in an object.

```
int_list = [1, 2, 3, 4, 5]
print(len(int_list))

float_tuple = (12.5, -2, 1.25, 0.5)
print(len(float_tuple))

print(len('Hello world!'))
string = "d e g a b l c f i h k j n"
print(len(string))

str_set = set('abcd')
print(str_set, len(str_set))
```

abs(num)

The **abs()** function returns the absolute value of the specified number.

```
print(abs(-12))  
print(abs(12))  
print(abs(-0.5))  
print(abs(0.5123))  
print(abs(False))  
print(abs('-12'))
```

round(float_num)

The **round()** function returns a floating point number that is a rounded version of the specified number, with the specified number of decimals.

```
print(round(-12.8765, 2))  
print(round(12.1245, 5))  
print(round(-0.5342, 2))  
print(round(0.5123, 2 ))  
print(round(False, 1))  
print(round('-12', 5))
```

sum(num_list)

The **sum()** function returns a number, the sum of all items in an **list**.

```
int_list = [1,2,3,4,5]
print(sum(int_list))

float_list = [12.5, -2, 1.25, 0.5]
print(sum(float_list))

num_string = "12 5.5 -2.5 11"
num_str_list = num_string.split()
num_float_list = list(map(float, num_str_list))
print(sum(num_float_list))
```

max(num_list)

The **max()** function returns the item with the highest value, or the item with the highest value in an iterable.

```
int_list = [1,2,3,4,5]
print(max(int_list))

float_list = [12.5, -2, 1.25, 0.5]
print(max(float_list))

num_string = "12 5.5 -2.5 11"
num_str_list = num_string.split()
num_float_list = list(map(float, num_str_list))
print(max(num_float_list))
```

min(num_list)

The **min()** function returns the item with the lowest value, or the item with the lowest value in an iterable.

```
int_list = [1,2,3,4,5]
print(min(int_list))

float_list = [12.5, -2, 1.25, 0.5]
print(min(float_list))

num_string = "12 5.5 -2.5 11"
num_str_list = num_string.split()
num_float_list = list(map(float, num_str_list))
print(min(num_float_list))
```

sorted(list)

The **sorted()** function returns a sorted list of the specified iterable object.

```
int_list = [1,2,3,4,5]
sorted_i_list = sorted(int_list)
print(sorted_i_list)

float_list = [12.5, -2, 1.25, 0.5]
sorted_f_list = sorted(float_list)
print(sorted_f_list)

string = "d e g a b l c f i h k j n"
str_list = string.split()
sorted_s_list = sorted(str_list)
print(sorted_s_list)
```

map(x, list)

The **map()** function executes a specified function for each item in an iterable. The item is sent to the function as a parameter.

We can use it to convert all of list items to specific type.

```
str_list = ['-1', '13.5', '-2.1', '11']  
print(str_list)
```

```
float_list = list(map(float, str_list))  
print(float_list)
```

```
final_list = list(map(lambda x: int(x)**2, float_list))  
print(final_list)
```
